9 Abstract

- 10 Aim: To quantify the explanatory power of heterogeneity in predicting plant species richness and turnover
- 11 here in the Greater Cape Floristic Region and in the Southwest Australia Floristic Region. We compare the
- 12 environmental heterogeneity in each region, how species richness and turnover interact in each region to
- 13 produce the observed patterns of richness, and what different forms of environmental heterogeneity better
- 14 predict richness in each region. We expect the Cape to be more heterogeneous in most environmental axes,
- 15 and at a finer grain, such that the consequent high levels of species turnover explain the Cape's greater
- 16 species richness per unit area. We also conjecture that edaphic heterogeneity will be an important factor in
- 17 predicting richness in SW Australia.
- 18 Location: The Greater Cape Floristic Region (GCFR) in southwest Africa, and the Southwest Australia
- 19 Floristic Region (SWAFR)
- 20 **Taxon:** Vascular plants
- Methods: Geospatial data, floral occurrence data \rightarrow regression analyses, non-parametric statistics
- 22 Results:
- 23 Main conclusions:
- 24 Keywords: biodiversity, environmental heterogeneity, fynbos, Greater Cape Floristic Region, kwongan,
- 25 macroecology, species richness, species turnover, vascular plants, Southwest Australia Floristic Region

30 1 Introduction

- 31 Biodiversity represents the variety of living things, and the variety of ecological and evolutionary processes
- 32 responsible for it (Bøhn & Amundsen, 2004). Studying the distribution of biodiversity in space is a major
- 33 avenue of biological research (???; Kreft & Jetz, 2007). Regional-scale geographic patterns in species richness

have long been studied, particularly in biodiversity hotspots (Cook et al., 2015). The spatial distribution of

35 species richness can be explained in terms of the physical environment. Properties of the environment have

- 36 been suggested to influence species richness in three ways: (i) productivity, water, and energy to enable
- 37 organismal growth, and resources (i.e. niche space) to support a wider range of species (Gaston, 2000; Kreft
- 38 & Jetz, 2007; Mouchet et al., 2015); (ii) stability, which enables species' persistence; and (iii) heterogeneity,
- 39 which enables ecological speciation and possible barriers to gene flow, and with a wider variety of
- 40 environments to facilitate species' co-existence (Thuiller et al., 2006; Mouchet et al., 2015; Cramer &
- 41 Verboom, 2016). The physical environment, then, can be used to explain species richness in a
- 42 local-deterministic sense, and in a historical context (Ricklefs, 1987).
- 43 The maintenance of species richness, particularly the coexistence of high numbers of species in biodiversity
- 44 hotspots, is often regarded as "paradoxical" (Hart et al., 2017), and is a central problem in ecology (Ricklefs,
- 45 1987; Kreft & Jetz, 2007; Hart et al., 2017). Species richness is constrained by the ability of habitats to
- 46 support a variety of species—its ecological carrying capacity (Mateo et al., 2017). This is exemplified in
- 47 approaches to modelling species richness as a function of environmental predictors in a correlative framework
- 48 ("macro-ecological models"; Mateo et al., 2017). Macro-ecological models of species richness implicitly
- 49 assume that communities are saturated, following species-area and species-energy relationships, and at
- 50 equilibrium with the environment (Mateo et al., 2017).
- A solution to the paradox of species coexistence is environmental heterogeneity (EH): a more heterogeneous
- 52 environment has a larger environmental space, and can thus facilitate co-existence between species at the
- 53 scale of that heterogeneity. EH can also stimulate ecological speciation, should the region be environmentally
- 54 stable over evolutionary time-scales. Heterogeneity in the physical environment is known to be positively
- associated with species richness (Rensburg et al., 2002; Hart et al., 2017), and has been demonstrated to do
- 56 so across many taxa—e.g. Canadian butterflies (???), European vertebrates (Mouchet et al., 2015), South
- 57 African birds (Rensburg et al., 2002), in communities along marine continental margins (Levin et al., 2010),
- 58 French scarab beetles (Lobo et al., 2004), and for global terrestrial plants (Kreft & Jetz, 2007). The spatial
- scale of heterogeneity, or "grain" of the environment, is important to consider (Hart et al., 2017), in the same
- 60 way that the spatial of absolute environmental conditions has also been considered (???; Baudena et al.,
- 61 2015; Mouchet et al., 2015). Species co-existence and biodiversity maintenance is indeed suggested to be
- 62 scale-dependent (Hart et al., 2017).
- 63 EH is often under-represented in macro-ecological models of species richness, and has recently been found to
- 64 explain up to ca. 95% of biome level species richness across South Africa (Cramer & Verboom, 2016).
- 65 Models that include EH yield better estimates of the richness of the Cape flora, as they account for the role
- 66 heterogeneous environments such as those in the Cape facilitate species coexistence (Thuiller et al., 2006;
- 67 Cramer & Verboom, 2016). Mediterranean-type terrestrial biodiversity hotspots, such as the Cape flora
- 68 included in the models by Cramer & Verboom (2016), present interesting study systems in which to
- 69 investigate the relationship between the environment and species richness. These systems exhibit far greater
- 70 species richness than predicted by their areas, productivities and latitudes (Cowling et al., 1996; Kreft &
- 71 Jetz, 2007). There are five Mediterranean biodiversity hotspots on Earth: the California Floristic Province,
- 72 the Mediterranean Basin, the Chilean Winter Rainfall-Valdivian Forests, the Greater Cape Floristic Region,
- and the Southwest Australia Floristic Region (Cowling et al., 1996; Hopper & Gioia, 2004; Cook et al., 2015).
- 74 These ecosystems have regular fire-cycles (Cowling et al., 1996), climatic buffering, and long term stability
- 75 (Kreft & Jetz, 2007), shrubby, sclerophyllous flora (Hopper & Gioia, 2004). Together, they account for ca.
- 76 20% of global vascular plant species, yet only ca. 5% of global land surface areas (Cowling et al., 1996).
- 77 Various hypotheses have been proposed to explain the high levels of plant species richness in these regions
- 77 Various hypotheses have been proposed to explain the high levels of plant species fitniness in these regions 78 (Cook et al., 2015). The species accumulation hypothesis states that the stability of these regions has allowed
- 79 many species to accrue. The species co-existence hypothesis states that these hotspots may facilitate greater
- 80 degrees of species co-existence in smaller spatial areas, due to fine-scale heterogeneity in their environments.
- degrees of species to existence in smaller species are some neutrogeners, in their environments
- 81 Indeed, EH has evolutionary implications too, stimulating ecological speciation across sharp environmental
- 82 gradients.
- 83 Both the Southwest Australia Floristic Region (SWAFR) and the Greater Cape Floristic Region (GCFR) are
- 84 Mediterranean-type biodiversity hotspots, particularly in terms of plant species. Where the GCFR (with an
- area of ca. $189,000 \text{ km}^2$) is known to contain about 11,400 plant species (about $0.060 \text{ species per km}^2$), the

SWAFR (area of ca. 270,000 km²) has about 3,700 species (0.014 species per km²) (???). So, the GCFR has ca. 4.3 times as many species per km² as the SWAFR. The GCFR and SWAFR are appropriately often 87 compared, due to the similarities between their environments (e.g. oligotrophic soils, an oceanically buffered 88 moderate climate) and their plants' ecologies (Hopper & Gioia, 2004). These two regions present unique flora 89 90 out of the five Mediterranean systems, with high levels of endemism (Cowling et al., 1996), and many obligate fire-adapted species (Cowling et al., 1996). Similarities withstanding, the SWAFR is topographically 91 and edaphically distinct from the GCFR. The SWAFR former is topographically rather uniform 92 (i.e. flat)—uniquely so among the world's five Mediterranean-climate regions (Hopper & Gioia, 2004)). The 93 SWAFR possesses a mesoscale chronosequence dune system (Laliberte et al., 2014; Cook et al., 2015), while 94 95 the GCFR is mountainous, topographically heterogeneous, and therefore associated with a large degree of spatial climatic variability, with a fine-scale mosaic of geologies and soils (Cowling et al., 1996; Cramer et al., 96 2014; Verboom et al., 2017). Both regions have sources of edaphic heterogeneity, but at different scales. This 97 edaphic variability may aid in explaining the species richness in these regions (Beard et al., 2000; Verboom et 98 al., 2017). EH can stimulate ecological speciation, should the region be stable over evolutionary time-scales, 99 as is likely the case in both the GCFR and the SWAFR (Wardell-Johnson & Horwitz, 1996; Hopper & Gioia, 100 2004; Lambers et al., 2010; Cramer et al., 2014; Laliberte et al., 2014; Cook et al., 2015). For the GCFR, this 101 richness is largely known to result from long term climatic stability, and fine grain variation in geology and 102soils (Cramer et al., 2014). The question thus arises whether heterogeneity is a significant contributor to 103 SWAFR species richness as is likely the case in the GCFR. In the absence of topographic variability in the 104 105 SWAFR, it is proposed that the heterogeneity of that region is due to the juxtaposition of soil types (Laliberte et al., 2014; Cook et al., 2015), creating extreme edaphic variation. 106

107 1.1 Hypothesis-v1

- 108 Our main hypothesis is that the greater abiotic heterogeneity in the Cape, and the finer grain of that
- 109 heterogeneity, compared to that of the SWA, accounts for the Cape's greater species richness per unit area.
- 110 We expect the relationships between EH, species richness, and species turnover in these two regions to
- demonstrate this. As stated above, heterogeneous environments can (i) support diverse species assemblages,
- and (ii) stimulate ecological speciation. Thus, we expect species richness to covary with heterogeneity.
- 113 Additionally, as one moves across a heterogeneous landscape, we expect to find greater turnover in
- 114 community composition, as different environments support different species. Thus, areas of greater turnover
- should also be more rich, due to potential complementarity between neighbouring communities increasing
- total richness. Thus, we expect that EH positively influences species richness and species turnover, and that
- 117 species turnover itself positively influences species richness.

118 1.2 Hypothesis-v2

- 119 Aim: This study investigates the role EH plays in explaining vascular plant species richness in the Cape and
- 120 SWA. We compare the relative importance of heterogeneity between the two regions, as heterogeneity has the
- 121 evolutionary role of facilitating speciation, and the ecological role of supporting diverse species assemblages.
- 122 Spatial scale of that heterogeneity is also considered, as the heterogeneity-richness relationship can vary with
- 123 habitat grain-size.
- 124 Our hypotheses concern the Cape and SWA's environments and floras. Our main hypothesis is that the Cape
- 125 possesses greater abiotic heterogeneity, and at finer grain, compared to SWA, such as to explain the Cape's
- 126 greater species richness per unit area, and proposed greater levels of species turnover between areas. We also
- conjecture that the heterogeneity that predicts species richness in SWA will be more pronounced in terms of
- edaphic variables. Here we attempt to assess six key predictions of this hypothesis, additionally investigating
- 129 a seventh prediction to test the conjectured role of edaphic heterogeneity in SWA. Dealing with the two
- 130 regions' environments, we assess (i) whether the Cape environment is more heterogeneous than that of SWA
- 131 and (ii) whether the Cape environment has more pronounced heterogeneity at finer scales than that of SWA.
- Dealing with the distribution of species in the two regions, we assess (iii) whether the Cape exhibits greater
- 133 levels of species turnover between areas, such as to (iv) explain the greater species richness per unit area of

- the Cape compared to SWA. Relating each regions' environment and flora, we finally assess (v) whether
- species richness and species turnover are adequately predicted by EH in both regions and whether (vii)
- 136 Species richness and species turnover are better predicted by different forms of EH in either region (e.g. the
- importance of edaphic heterogeneity in SWA).
- 138 ...
- 139 We employ classical statistical methods to analyse publicly available geospatial and species occurrence
- 140 datasets.

141 2 Materials and methods

142 **2.1 Overview**

- 143 These analyses required definitions of the boundaries of the two regions, environmental data for each, and
- 144 geospatially-explicit vascular plant occurrence records, all based on publicly available data. The
- environmental variables chosen (Table 1) for this study were intended to cover a reasonable spread of
- 146 climatic, edaphic, and ecologically relevant environmental axes, and are not intended to be exhaustive. We
- 147 selected variables describing topography (elevation), productivity (NDVI), soil status, and climate and
- 148 climatic seasonality.
- We carried out this investigation using four principal spatial scales: 0.05° x 0.05° squares (the finest common
- resolution among the environmental data sources used), quarter degree squares (QDS) (Larsen et al., 2009),
- 151 half degree squares (HDS) (Larsen et al., 2009) and three-quarter degree squares (3QDS). Note, at least for
- the Cape, most plant occurrence records are only accurate to QDS level. Thus, any analysis involving species
- 153 data was necessary limited to scales above and including QDS. Analyses were performed in R v3.5.0 (R Core
- 154 Team, 2018). Version-numbers of specific R packages used are presented in the bibliography, or in text where
- 155 applicable.

156 2.2 Environmental data sources

- 157 Geospatially-explicit raster layers were acquired for a selection of environmental variables (Table 1), for the
- 158 regions of interest. Here, the GCFR was treated as the areas occupied by the Succulent Karoo and Fynbos
- biomes in the current delineation of South Africa's biome boundaries (Mucina & Rutherford, 2006). The
- 160 SWAFR was treated as the areas occupied by the Southwest Australia savanna, Swan Coastal Plain Scrub
- 161 and Woodlands, Jarrah-Karri forest and shrublands, Southwest Australia woodlands, Esperance mallee, and
- 162 Coolgardie woodlands in the World Wildlife Fund Terrestrial Ecoregions dataset (Olson et al., 2001) in order
- to closely match the currently delineated SWAFR (Gioia & Hopper, 2017, Hopper & Gioia (2004)). For the
- sake of readability, we shall refer to the GCFR and SWAFR simply as the Cape and SWA from hereon.
- Raster data were re-projected to a common coordinate reference: WGS84 (NIMA, 2000), using the "rgdal"
- 166 (???) package in R (R Core Team, 2018). All data were re-sampled to 0.05° resolution using the "resample"
- 167 function in the R package "raster" (???), with the "bilinear" method.
- An emphasis was made on using satellite-derived environmental data in this work, in order to minimise
- differences in data quality and methodologies between the Cape and SWA. Additionally, satellite-derived
- data have been shown to benefit regional-scale species distribution models (Deblauwe et al., 2016), thus
- motivating their use in this regional-scale study. The environmental data used in this study were derived
- 172 from NASA's SRTM digital elevation model (Farr et al., 2007), NASA's MODIS/Terra spectroradiometric
- 173 data for land surface temperature and NDVI, the Climate Hazards Group's CHIRPS rainfall dataset (Funk
- et al., 2015), and the International Soil Reference and Information Centre's SoilGrids250m edaphic dataset (Hengl et al., 2017) (Table 1). SRTM and MODIS are entirely derived from satellite measurements, whereas
- (Hengl et al., 2017) (Table 1). SRTM and MODIS are entirely derived from satellite measurements, who CHIRPS is interpolated from weather station data with satellite-derived radiometric measurements.
- 177 SoilGrids250m is a machine-learning derived product, based on soil measurements as a function of many

- 178 covariates, including MODIS and STRM sources (see Hengl et al., 2017), using random-forests and other
- 179 classification-tree-based methods, including gradient-boosting. For the soil data considered here (Table 1),
- 180 we used depth-interval weighted average values as the value for a particular soil variable in a given place.
- 181 Climatic and spectral data arise from satellites monitoring properties of the Earth's surface through time.
- We therefore use the mean annual values for rainfall, surface temperature, and NDVI across space in our
- analyses. Pronounced seasonality of rainfall is a known feature of Mediterranean systems (???). known
- to to timing, namely precipitation in the driest quarter (PDQ) and temperature in the ... describe!->

185 2.3 Plant occurrence data

- 186 Geospatially-explicit records of vascular plant occurrences were downloaded from the Global Biodiversity
- 187 Information Facility (GBIF, Table 1). Queries were made for tracheophyte records from within the borders of
- the Cape and SWA as treated here (GBIF, 24 July 2017, GBIF (24 July 2017)). Only records with defined
- 189 species and intra-specific ranks were kept. Intra-specific occurrences were treated as simply being
- 190 representative of their species. This resulted in 1 unique species names in the Cape, and 1 in SWA.
- 191 We cleaned these data using the R package "taxise" (???, (???)) to check that these species names had
- 192 accepted-status among taxonomic databases. I queried two major taxonomic databases: the Global Name
- 193 Resolver (GNR), and the Taxonomic Name Resolution Service (TNRS). Should one of either service return
- 194 at least one match for a given name, then that name was deemed accepted. Those names for which no full
- binomial matches were found in either database were excluded from the final list of species. The number of
- 196 species names excluded totalled at 1 and 1 for the Cape and SWA respectively. Especially for SWA, these
- 197 numbers may be deemed appreciably high. But, the occurrence records that would be dropped, as a
- 198 consequence of these names' removals, seemed to be distributed randomly in geographic space in both
- 199 regions. As such, any effect of the loss of these records in this analysis is uniform within the two regions.
- 200 After the unaccepted names were removed, it was important to ensure that a species was not listed under
- 201 multiple synonyms. Such cases would skew the species richness data used in this study. In light of this, the
- 202 remaining names were queried in the Tropicos and Integrated Taxonomic Information System (ITIS)
- 203 databases for their known synonyms, using "taxize". These were collated to produce a nomenclatural
- 204 "thesaurus" for the Cape and SWA species. This consisted of a list of the accepted species names in a region,
- each associated with a list of known synonyms. I amended species' names in the GBIF occurrence data, in
- 206 order ensure species were listed under only one of these synonyms, as follows: For each entry in the
- 207 thesaurus, for each synonym of that entry, if that synonym appeared in the GBIF species list, I replaced all
- 208 appearances of that synonym in the species list with the original name from the thesaurus-entry that that
- 209 synonym came from.
- 210 Lastly, I removed any species from both regions that are invasive aliens or non-indigenous. Alien species lists
- 211 for plants in South Africa and Australia were acquired from the IUCN's Global Invasive Species Database
- 212 (http://www.iucngisd.org/gisd/).
- 213 The final total plant species richness in each region was 12991 and 8074 for the Cape and SWA respectively.
- 214 These final collections of species occurrence records were converted to raster-layers, wherein pixel-values
- 215 represented the species, genus and family richness of vascular plants within that pixel. These rasters were
- 216 produced at QDS, HDS, and 3QDS resolutions.

217 **2.4** Analyses

218 2.4.1 Quantifying environmental heterogeneity

- 219 First, in order to assess predictions (i) and (ii), we needed to describe the EH in both regions. Using the R
- 220 package "raster" (???), we used a modified version of the "roughness" index in the "terrain" function: for a
- 221 three by three neighbourhood of cells, our index of roughness is the average square-root of the squared
- 222 difference between each of the n neighbour cells' values x_i and the central focal cell's value x_{focal} :

$$Roughness = \frac{1}{n} \sqrt{\sum_{i=1}^{n} (x_{focal} - x_i)^2}$$
 (1)

Note, in order to use as much data from within regions' borders as possible, roughnes swas computed if a 223 focal cell had at least one neighbour cell—that is, roughness is defined where $n_{x_{focal}} \geq 1$. Using this index of 224 heterogeneity, we produced raster layers of each of our nine environmental variable's heterogeneity. We 225 226 compared the distributions of roughness values in each variable in each region with non-parametric Mann-Whitney U-tests, as almost all variables could not be normalised by log-transformations. We also 227 compare the effect size of the Cape vs SWA using the "common language effect size" (CLES), using the R 228 package "canprot". The CLES is the proportion of all pairwise comparisons between two sample groups 229 observations where one group's value is greater than the other. In our case, of all pairwise comparisons of a 230 231 variable's roughness values between the Cape and SWA, we calculated the CLES as the proportion of pairs where Cape roughness values were greater than that of SWA. This allowed us to assess prediction (i). To 232 compare the spatial scales of heterogeneity (prediction [(ii)][Hypothesis-v2) between each region, we repeated 233 this analysis at all four spatial scales. Once again, this entailed recalculating the roughness layer for each 234 variable after the original layer (0.05 degrees resolution) had been rescaled to each of the coarser resolutions. 235

2.4.2 Relating species richness and species turnover

236

Regarding predictions (iii) and (iv), we wished to compare the relative importance of species turnover in each region as a predictor of species richness.

First, for (iii), we compared the degree of species turnover in general in each region by computing all pairwise
Jaccard distances (???) between QDS' communities. We then regressed these turnover values for each pair
of cells against the physical distance between the centres of those cells. The range of turnover values was
found to be highest at small distances (Figure 1a), and indeed complete species turnover between cell pairs
was observed at all distances. Thus we used quantile regressions of the 5% quantile of species turnover as a
function of geographic distances (using "quantreg" (???) in R). This allowed us to compare the lower bounds
of species turnover between the Cape and SWA.

Regarding prediction (iv), to test how turnover between sites predicts richness across rites, we regressed the 246 species richness in coarse scale cells against the average richness of and average turnover between the 247 constituent fine scale cells within a the coarse scale cell. Moreover, average turnover between fine scale cells 248 excluded turnover values between a cell and itself (necessarily 0), and only included turnover values between 249 between cell-pairs once (i.e. between cells a and b and not again between b and a, as these are necessarily the 250 same). We focussed on this relationship with HDS as the coarse scale and QDS as the fine scale—as there 251 are four QDS within each HDS, and QDS was the highest precision to which our species data were recorded. 252 Mean QDS richness for a given HDS-cell is based on four QDS-cells. Mean QDS turnover for a given HDS-cell is based on the turnover between $n = {j=4 \choose 2} = 6$ QDS pairs (namely pairs $QDS_{1,2}$, $QDS_{1,3}$, 253 254 $QDS_{1,4}, QDS_{2,3}, QDS_{2,4} \text{ and } QDS_{3,4}$). 255

256 Thus, we regress coarse scale richness as follows:

$$\widehat{S_{HDS_i}} = \beta_0 + \beta_1 \overline{S_{QDS}}_i + \beta_2 \overline{T_{QDS}}_i + \beta_3 SW A_i + \beta_4 \overline{S_{QDS}}_i SW A_i + \beta_5 \overline{T_{QDS}}_i SW A_i + \epsilon_i$$
(2)

where $\epsilon \sim N\left(\overline{x}, \sigma^2\right)$, and $\overline{S_{QDS}}$ is log(x+1)-transformed. This model allows us to compare the spatial-scaling drivers of species richness in either region: whether coarse scale increases in species richness are determined more by (a) being composed of richer—but more similar—communities or by (b) being composed of many different communities. These represent the two logical extremes.

2.4.3 Predicting species richness and turnover with environmental heterogeneity

262 3 Results

3.1 Describing environmental heterogeneity numerically across scales

- Across all variables considered, the Cape is more environmentally heterogeneous in the majority of pairwise
- 265 comparisons of grid-cells (CLES > 0.50, Mann-Whitney U-test: P < 0.05, Figure 1). The Cape is thus more
- 266 environmentaly heterogeneous than SWA overall, but the degree to which it is more heterogeneous varies
- 267 between environmental variables. These effects vary somewhat with the spatial scale concerned. In some
- 268 variables, the differentiation between Cape and SWA heterogeneity lessens at coarser scales (Figure 1).
- 269 Indeed, when comparing the overall ranking and medians of Cape vs SWA roughness values for each variable,
- 270 we only find non-significant differences at the coarser 3QDS scale (Mann-Whitney U tests, P > 0.05, Figure
- 271 1).

294

261

263

- 272 Most obviously, and as expected, topographic heterogeneity is greatest in the Cape (Figure 1a). Though
- 273 SWA has a slightly wider distribution of elevational roughness values at coarse scales (e.g. 3QDS, Figure 1a)
- 274 compared to fine scales (0.05°) , so does the Cape. As such, the relative difference between the two regions
- seems invariant with spatial scale ($CLES \approx 0.95$, Figure 1).
- 276 This concurs with our expectations, as the Cape is mountainous and known to have steep elevational
- 277 gradients (???), while SWA is much more topographically uniform.
- 278 Intuitively, then, elevation serves as a "benchmark test" for our comparisons of EH here, as it is well known
- and expected that the Cape should be more elevationally heterogeneous than SWA. Additionally, we can
- 280 conclude that although there are greater extreme values of Cape elevational roughness at 0.05° x 0.05° scales,
- 281 larger sections of land (i.e. 3QDS-cells) are are more different from each other in the Cape than the same
- 282 sized sections are different from each other in SWA.
- 283 Climatic heterogeneity presents less differentation between the Cape and SWA than elevational roughness,
- though still the Cape predominates (Figure ??b). Notably, the difference between Cape and SWA mean
- 285 annual rainfall and land surface temperature heterogeneity lessens when considered at coarse spatial scales
- 286 (3QDS scale, Figure ??b). Rainfall seasonality (PDQ), however, is similarly more heterogeneous in the Cape
- 287 across all spatial scales considered.
- 288 Biological productivity, as measured by NDVI, varies spatially to a similar extent in the Cape and SWA
- 289 (i.e. is more similarly heterogeneous, CLES < 0.60, Figure 1c).
- 290 Concerning edaphic variables (Figure 1d), the Cape and SWA are similarly heterogeneous at coarser scales,
- 291 particularly in terms of CEC and Soil C.
- 292 We can differentiate the Cape and SWA environments based on which environmental axes are more
- 293 heterogeneous in either region, as they differ somewhat in this regard.

3.2 Species richness as determined by species turnover

- 295 Following quantile regressions of the 5%-quantile of pairwise species turnover against the distance between
- 296 pairs' sites (Figure 2a), there is evidence that SWA exhibits a lower lowermost-bound of observed species
- 297 turnover. This is because of the relative positive influence of a site's being "from the Cape", as opposed to
- SWA, on the 5%-quantile of species turnover ("Cape"-term, P < 0.001, Table 2). As expected, species
- turnover was greatest between distant pairs of QDS (P < 0.001, Table 2, Figure 2a).
- 300 When plotting coarse scale richness (HDS) against fine scale richness and turnover (QDS) (Figure 2b,c), we
- 301 see that for a mean QDS richness, Cape HDS are generally more species rich than SWA HDS. Also, for a
- 302 given mean QDS turnover, Cape HDS are generally more species rich than SWA HDS. For the sake of
- 303 interpretation, it is appealling to think of the graph inverted: for a given HDS richness (taken as the

- 304 horizontal axis now), the Cape is less rich and has less turnover between QDS than SWA. However, the
- 305 graph was plotted as presented for the sake of agreement with the regression model (below), which does
- 306 support the sentiment of an inverted interpretation.
- 307 Following the regressions of coarse scale richness (HDS) against fine scale richness and turnover (QDS)
- 308 (Equation (2)), we see a significant negative interaction between SWA and mean QDS richness (Table 3),
- 309 supporting the visually obvious difference between the Cape in SWA in Figure 2b.
- 310 Assume HDS scale richness is the integration of QDS scale richness and turnover between QDS. We can see
- 311 that HDS richness "saturates" as a function of QDS richness at a lower HDS richness level in SWA than in
- 312 the Cape. Alternatively, the QDS richness required to attain a given HDS richness is much lower in the
- 313 Cape—Cape QDS richness is more "powerful" and has a greater impact on HDS richness than QDS richness
- in SWA. In other words: the rate of change in HDS richness ~ QDS richness in the Cape is faster, as is
- evident in the negative slope effect of the SWA on the logarithmic slope relative to the Cape.
- 316 Now for HDS richness ~ QDS turnover. HDS richness declines with increasing turnover. Why? Let us turn
- 317 the process on its head: why does high turnover arise from low richness QDS? Well, when richness is low,
- 318 possible opportunities for high turnover increase.

319 4 Discussion

- 320 Conclusion: The Cape is more generally environmentally heterogeneous than the SWA, as expected (see
- 321 prediction (i)). Though, there are cases where the SWA is arguably at-least-as-heterogeneous as the Cape,
- 322 and we can observe here extreme regions of high edaphic heterogeneity, at fine scales, in SWA. These surpass
- 323 the edaphic heterogeneity of the Cape, supporting our seventh prediction/conjecture.
- 324 We also have support for prediction (ii), as seen in Fig. ??.
- 325 I have provided support for the hypothesis that the difference in plant species richness between the GCFR
- and SWAFR is accounted for by the fact that the GCFR is more abiotically heterogeneous than the SWAFR.
- 327 As expected, the GCFR is shown to possess (i) a quantifiably more heterogeneous environment, and (ii) is
- 328 heterogeneous at a finer spatial scale than the SWAFR. I have shown that vascular plant species richness (iii)
- 329 can be explained in terms of environmental conditions, including environmental heterogeneity, in both the
- 330 GCFR and SWAFR. Also, I have shown that (iv) the set of environmental axes that explain plant species
- 331 richness, both absolute and as heterogeneity, differs between the GCFR and SWAFR. These findings
- 332 contribute towards an understanding of the ecological conditions that facilitate species coexistence (and likely
- 333 stimulate ecological speciation) in these two regions.
- 334 These two regions present differentiable environmental spaces, each with heterogeneity varying across spatial
- scales. The clear separation of the regions' topographic features is as expected (Figures ??A, ??). Indeed,
- 336 topography seems to be the most striking distinction between the regions. The Cape region has been found
- 337 previously to have the second highest median topographic heterogeneity of the five Mediterranean-climate
- 338 regions (Bradshaw & Cowling, 2014). The GCFR has a much wider range of scales exhibited in the
- 339 heterogeneity across its environmental axes. Notably, each region has finer scale heterogeneity in some
- variables, and coarser scale in others—neither region is necessarily more fine or coarse than the other, as it
- 341 depends on the variable concerned. BRT-models of species richness in both regions reveal species richness to
- depend on those environmental axes that differentiate the two regions (Figures ??), ??). The importance of
- variables is also shown to vary with spatial scale (Figure ??), as previously suggested may be the case when
- modelling geographic patterns of biodiversity (Baudena et al., 2015). Indeed, as Cowling et al. (1996)
- describes differing patterns of species richness across spatial scales, so do the predictors of those patterns
- 346 vary with scale (Hart et al., 2017).
- 347 The fact that a combination of absolute and roughness variables is also as predicted by the hypothesis in this
- study. In the models developed by Cramer & Verboom (2016) for South Africa, roughness in topography was
- 349 largely superseded as an important predictor of species richness by other roughness variables. My models,
- 350 however, did not show this. Similar to the study by Rensburg et al. (2002), my models revealed roughness in

topography and other variables to be important. Although, Rensburg et al. (2002) considered differences within pixels, as opposed to this study, which considered differences between pixels. My models, those of Cramer & Verboom (2016), and those of Rensburg et al. (2002), do not all concur as to the role of roughness in elevation vs. more biologically meaningful variables in explaining species richness. The source of these discrepancies is unclear, though no doubt complex. The complements of environmental variables and methodologies used in these studies do differ, limiting extensive comparison between these analyses.

The determinants of vascular plant species are shown to be region specific (Figures ??, ??, ??). The 357 358 importance of MAP and roughness in rainfall seasonality (PCV) in predicting richness in the SWAFR (Figure ??I, ??J), aligns with the steep climatic gradients observed there (Cook et al., 2015). The soil 359 variables that determine plant species richness in the model for the SWAFR (Figures ??K, ??L) differ to 360 those that determine richness in the GCFR (Figures ??G, ??H), further highlighting the edaphic differences 361 362 between these two regions. Although both are nutrient leached systems, the SWAFR is flat, with soil-chronosequences (Laliberte et al., 2014; Cook et al., 2015), while the GCFR is mountainous (Cowling et 363 364 al., 1996; Cramer et al., 2014; Verboom et al., 2017). The importance of roughness in soil density, and absolute texture, in the SWAFR (Figures ??K, ??L) highlights the changes in soil that are associable with 365 age of the substrate (e.g. particle size) as being biologically relevant to species richness. The positive effect 366 367 of soil clay content on species richness in the SWAFR aligns with the findings of Laliberte et al. (2014) that 368 richness in the SWAFR increases with soil age.

NDVI is more heterogeneous across the GCFR than the SWAFR (Figures ??A). The fact that thermal 369 370 variables tend to be more rough in the GCFR (Figure ??A) is likely due to possible covariance of the MODIS/Terra products with topography, as MODIS data used here describes land surface temperature. As 371 the GCFR is topographically rugged, the roughness of NDVI may arise from this. Despite this, NDVI is an 372integrating variable, which captures information about productivity, light availability, and soil nutrients 373 (Power et al., 2017). The fact that absolute NDVI contributes to predicting species richness in the GCFR, 374 375 especially at finer spatial scales (Figure ??E) demonstrates the role of ecological productivity in facilitating the coexistence diverse species assemblages. Environmental heterogeneity, then, is integral to explaining 376 patterns of species richness, but must be considered along with resource- and energy-availability axes. In so 377 much as a diverse environmental space supports more species, the materials and productivity required for 378 biota to thrive are also needed to support species (????; Gaston, 2000; Bøhn & Amundsen, 2004; Kreft & 379 380 Jetz, 2007). As such, my findings, along with those of previous studies (Rensburg et al., 2002; Thuiller et al., 381 2006; Kreft & Jetz, 2007; Cramer & Verboom, 2016), suggest that there is ecological and evolutionary consequence to resource availability and environmental heterogeneity, in that they tend to be positively 382 associated with species richness. 383

The combined BRT-model of species richness for both regions reveals soil clay content as an important predictor, at coarse spatial scales, despite this variable not being particularly important within each region separately (Figure ??). Though this model does not strictly consider the regions as separate, this finding may indicate that the relationship between clay content and species richness differs between the regions. So far as clay content can be used to predict species richness, it matters more to those predictions when applied to large sections (i.e. coarse scales) of each regions.

Kreft & Jetz (2007) modelled global terrestrial vascular plant species richness, which focussed on primarily 390 absolute environmental values, underestimated the richness of the Cape flora. Though Kreft & Jetz (2007) 391 did include topographic heterogeneity in their predictor set, topography is often a proxy for more biologically 392 meaningful variables (Cramer & Verboom, 2016). This explains why the inclusion of these variables (393 e.g. roughness in mean annual precipitation) yields more accurate predictions of species richness. Indeed, 394 Thuiller et al. (2006) also included topographic heterogeneity. Cramer & Verboom (2016) described 68% of 395 species richness at the QDS scale across South Africa. Regarding the GCFR, depending on whether one 396 consults pseudo- R^2 (Table 3), the ratio of mean predicted to observed richness per grid-cell (Table 5), or the 397 distributions of predicted vs. observed richness values per grid-cell (Figure ??), I have achieved a similarly 398 suitable level of predictive accuracy. There is, though, still unexplained species richness in light of my models. 399 400 As Cramer & Verboom (2016), Rensburg et al. (2002), Thuiller et al. (2006), and Mouchet et al. (2015) have done, these macro-ecological models are a-historical. Evolutionary considerations of species richness in 401 geographic space are worthwhile, especially in regions with environments stable over evolutionary time.

The findings here are correlative. There are, however, many proposed mechanisms to explain the correlative signals demonstrated here. My findings support the hypothesis that Mediterranean systems' plant species 404 405 richness is a function of spatial variability in environmental conditions. This can stimulate diversification, and maintain that diversity by providing a range of habitats for species co-existence. Oligtrophic soils can 406 407 stimulate an increase in functional diversity, through the evolution of diverse nutrient acquisition strategies (Lambers et al., 2010; Verboom et al., 2017) (e.g. sclerophylly (Cramer et al., 2014; Cook et al., 2015)). An 408 aspect of the environment I have neglected to consider is fire, shown to also contribute to predictions here in 409 the GCFR (Cramer & Verboom, 2016). Cardillo (2012) have shown the structuring forces behind species 410 co-occurrence patterns, and thus likely species richness, differ between species-pairs with different post-fire 411 412responses and those with similar post-fire responses.

Though the GCFR was correctly predicted to have, on average, more species per grid-cell at HDS and 3QDS 413 414 scales than the SWAFR, this was not the case for QDS grid-cells (Table 5). This demonstrates that the GCFR is indeed overall more rich in plant species than the SWAFR, but a given HDS in the SWAFR 415416 contains fewer species than a given GCFR HDS. Thus, the greater richness in the GCFR is a product of greater turnover in species at spatial scales no more coarse than the HDS. Species turnover is an interesting 417aspect to species richness studies, as it species turnover is implicit to species-area and co-existence-area 418 419 relationships (Hart et al., 2017). One could expect patterns of endemism and species turnover to concur with 420 patterns in environmental heterogeneity to some degree.

Following from the understanding that functionally diverse assemblages, which are more likely to be more 422 species rich, are likely to arise and/or occur in areas with diverse ecological pressures (Molina-Venegas et al., 2015), one would expect, then, heterogeneous habitats such as those in Mediterranean-type biodiversity 423 hotspots to exhibit high levels functional beta diversity along steep environmental gradients (Molina-Venegas 424 et al., 2015). If the niches concerning these functions are phylogenetically conserved among those biota, then 425 one would also expect high levels of species and phylogenetic beta diversity along these gradients 426 427 (Molina-Venegas et al., 2015). This concurs with the notion put forward by Power et al. (2017), wherein megadiverse systems such as these represent the results of "phylogenetic niche conservatism on a 428 heterogeneous landscape". Thus, species and phylogenetic turnover should covary with environmental 429 heterogeneity in some way. Indeed, endemism, at certain scales, could also follow this pattern. Thuiller et al. 430 (2006) demonstrated that there is phylogenetic and biome related determinants of species richness. This 431 432 makes sense, in light of the difficulty of crossing biome boundaries in Mediterranean systems (Power et al., 433 2017). NDVI and light availability, and the heterogeneity therein, are associated with high levels of floristic turnover (Power et al., 2017). This may be indicative of ecological specialisation precluding species from 434 crossing these boundaries, thus increasing the level of endemism within a region, while also increasing the 435 level of turnover, and thus likely species richness, along environmental gradients. Although, this may be 436 debated. Beard et al. (2000) state that the high levels of endemism in SWAFR are function of habitat 437 438 specialisation to soil mosaics. Cf. Laliberte et al. (2014), who say that this endemism is likely due to environmental filtering along these soil turnover sequences, as opposed to the juxtaposition of specialised 439 species along soil gradients. 440

I have demonstrated support for the idea that environmental heterogeneity is positively associated with species richness, particularly Mediterranean systems. In the SWAFR and the GCFR, high levels of endemism and biodiversity are also likely the results of long-term landscape and climatic stability (Hopper, 1979). Thus, the roles of environmental variability through space, and stability through time, are the two main ways in which the environment relates to biodiversity in these regions.

446 Table captions

447 Captions are also repeated alongside their respective tables for readability.

448 **Table 1**

- 449 Georeferenced vascular plant species occurrence and environmental data sources used in this study.
- 450 Abbreviations are as follows: MAP, mean annual precipitation; PDQ, precipitation in the driest quarter;
- 451 CEC, cation exchange capacity.

452 Table 2

- Estimated coefficients and significances (P-value) following quantile regression of the 5%-quantile ($\tau = 0.05$)
- 454 of pairwise vascular plant species turnover (Jaccards distance) as a function of the geographic distance (km,
- 455 log-transformed) between QDS cells. The Cape term represents the difference between Cape and SWA
- 456 species turnover, for a given geographic distance.

457 **Table 3**

- 458 Estimated coefficients and significances (P-value) following multiple linear regression of HDS species richness
- 459 against the mean QDS species richness (log(x+1)-transformed) and turnover (Jaccards distance) within a
- 460 given HDS, of the form in Equation (2). The Cape was fit as the baseline, hence SWA represents the
- 461 categorical term here. This was model was better fitting than a similar model without a region category
- 462 ($\Delta AIC = 90.56$). Note, this model does not represent those curves plot in Figure 2 (there, the curves are
- 463 from simple linear regressions of the variables in each panel, separated by region).

464 Table 4

- 465 Comparisons of Akaike information criterion values (small sample-size-corrected, AICc) of various
- 466 geographically weighted regressions (GWR) of log-transformed species richness as a function of various sets
- 467 of environmental variables. Models were fit for the Cape and SWA richness and environmental data both
- 468 separately and together. GWR methods preclude the need for a categorical predictor for the Cape vs SWA.
- 469 as the longitudinal (and to a lesser extent latitudinal) differences between the regions allows local regression
- 470 coefficients in each region to differ.

471 Figure captions

472 Captions are also repeated alongside their respective figures for readability.

473 Figure 1

- 474 Comparisons of different types of environmental heterogeneity in the Cape and SWA—namely for (a)
- 475 elevation, (b) climatic variables, (c) NDVI and (d) soil variables—in each panel consisting of three sub-panels
- 476 per variable type. The upper row of panels shows example distributions of roughness values (Equation (1)),
- 477 showing the different extremes in environmental heterogeneity observed in each region when compared at fine
- 478 (0.05°) and coarse (3QDS) scales. Each distribution has under it area 1. Distributions were constructed with
- 479 Gaussian kernels, with bandwidth following Silverman's "rule of thumb" (???). In the lower row of panels,
- 480 these distributions of roughness values were compared between the Cape and SWA at each of the four spatial
- 481 scales, not just 0.05° and 3QDS, using non-parametric Mann-Whitney U-tests to test for differences. The
- 482 "common language effect size" (CLES, see text) describes these differences (b). U-tests for almost all
- 483 environmental variables yielded significant differences (P < 0.05) between Cape and SWA values (NS,
- 484 non-significant differences).

Figure 2

- 486 Regressions involving plant species richness and turnover. Species turnover (as Jaccards distance) between
- 487 QDS-pairs increases as pairs are more geographically separated (a). Species turnover was calculated for all
- 488 possible pairs of cells, but only the turnover values for a random 5000 pairs in each region have been plotted,
- 489 for clarity. Fitted lines represent the 5%-quantile regressions of turnover as a function of log-distance for each
- 490 region separately. Following a 5%-quantile regression of turnover as a function of log-distance with region as
- 491 a categorical variable (Table 2), a significant interaction between distance and region was found (P < 0.001),
- 492 such that the Cape positively effects the distance slope term. Scatter-plots of HDS-scale species richness
- 493 against the average QDS-scale richness in a given HDS (b) and the average species turnover between QDS in
- 494 a given HDS (c). Curves represent simples linear regressions of HDS richness against these two respective
- independent variables (note, mean QDS richness was log(x + 1)-transformed), separately for each region, for
- 496 illustration of the two regions' differences, for interpretation alongside Table 3.

592 Author contributions

- 593 MDC and GAV conceived the study question, which RVM investigated under their supervision for his BSc
- Hons project. The analyses and programming work were largely devised by RVM, with input from the other
- 595 authors, and was carried out by RVM. RVM wrote the first draft of the manuscript and all authors
- 596 contributed equally thereafter.

597 Tables

Table 1: Georeferenced vascular plant species occurrence and environmental data sources used in this study. Abbreviations are as follows: MAP, mean annual precipitation; PDQ, precipitation in the driest quarter; CEC, cation exchange capacity.

Variable	Source	Citation		
Plant species occurrences	GBIF	??, ??		
Elevation	SRTM v2.0	??		
NDVI	MODIS (MOD13C2)	??		
Climatic variables				
MAP	CHIRPS v2.0	??		
PDQ	CHIRPS v2.0			
Surface T	MODIS (MOD11C3)	??		
Soil variables (SoilGrids250m)				
CEC	CECSOL M $250 \mathrm{m}$??		
Clay	CLYPPT M $250 \mathrm{m}$			
Soil C	OCDENS M $250 \mathrm{m}$			
pH	PHIKCL M $250 \mathrm{m}$			

Table 2: Estimated coefficients and significances (P-value) following quantile regression of the 5%-quantile ($\tau=0.05$) of pairwise vascular plant species turnover (Jaccards distance) as a function of the geographic distance (km, log-transformed) between QDS cells. The Cape term represents the difference between Cape and SWA species turnover, for a given geographic distance.

Term	Estimate	P-value
Intercept	-0.311	< 0.001
log(Distance between cells)	0.093	< 0.001
Cape	0.388	< 0.001
$log(Distance between cells) \times Cape$	-0.026	< 0.001

Table 3: Estimated coefficients and significances (P-value) following multiple linear regression of HDS species richness against the mean QDS species richness (log(x+1)-transformed) and turnover (Jaccards distance) within a given HDS, of the form in Equation (2). The Cape was fit as the baseline, hence SWA represents the categorical term here. This was model was better fitting than a similar model without a region category ($\Delta AIC = 90.56$). Note, this model does not represent those curves plot in Figure 2 (there, the curves are from simple linear regressions of the variables in each panel, separated by region).

Term	Estimate	P-value
Intercept	-3062.297	< 0.001
log(Mean QDS richness + 1)	595.574	< 0.001
Mean QDS turnover	338.589	0.534
SWA	2905.604	0.001
$log(Mean QDS richness + 1) \times SWA$	-333.908	< 0.001
Mean QDS turnover \times SWA	-1246.109	0.073

Table 4: Comparisons of Akaike information criterion values (small sample-size-corrected, AICc) of various geographically weighted regressions (GWR) of log-transformed species richness as a function of various sets of environmental variables. Models were fit for the Cape and SWA richness and environmental data both separately and together. GWR methods preclude the need for a categorical predictor for the Cape vs SWA, as the longitudinal (and to a lesser extent latitudinal) differences between the regions allows local regression coefficients in each region to differ.

Model predictors	AICc	$\Delta AICc$	w_{AICc}
Cape:			
Absolute variables	2112.49	0.00	1.00
Non-elevation variables	2179.35	66.86	0.00
All	2192.59	80.10	0.00
Soil variables	2197.76	85.28	0.00
Roughness variables	2208.43	95.94	0.00
Non-soil variables	2218.08	105.59	0.00
Elevation	2267.30	154.81	0.00
Null	3099.37	986.89	0.00
SWA:			
Absolute variables	826.47	0.00	0.69
Non-elevation variables	828.29	1.82	0.28
All	833.44	6.97	0.02
Soil variables	835.92	9.45	0.01
Non-soil variables	848.57	22.11	0.00
Roughness variables	868.89	42.42	0.00
Elevation	970.19	143.73	0.00
Null	27172.21	26345.74	0.00
Both:			
Absolute variables	1286.27	0.00	1.00
Roughness variables	1338.16	51.89	0.00
Non-elevation variables	1364.26	77.98	0.00
Elevation	1371.30	85.02	0.00
Soil variables	1371.47	85.19	0.00
Non-soil variables	1380.38	94.11	0.00
All	1390.78	104.50	0.00
Null	1404.05	117.78	0.00

598 Figures

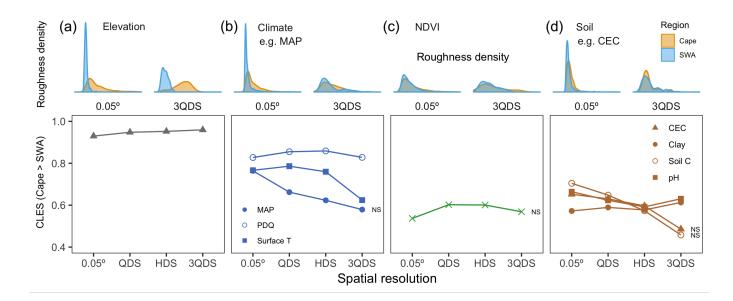

Figure 1: Comparisons of different types of environmental heterogeneity in the Cape and SWA—namely for (a) elevation, (b) climatic variables, (c) NDVI and (d) soil variables—in each panel consisting of three sub-panels per variable type. The upper row of panels shows example distributions of roughness values (Equation (1)), showing the different extremes in environmental heterogeneity observed in each region when compared at fine (0.05°) and coarse (3QDS) scales. Each distribution has under it area 1. Distributions were constructed with Gaussian kernels, with bandwidth following Silverman's "rule of thumb" (???). In the lower row of panels, these distributions of roughness values were compared between the Cape and SWA at each of the four spatial scales, not just 0.05° and 3QDS, using non-parametric Mann-Whitney U-tests to test for differences. The "common language effect size" (CLES, see text) describes these differences (b). U-tests for almost all environmental variables yielded significant differences (P < 0.05) between Cape and SWA values (NS, non-significant differences).

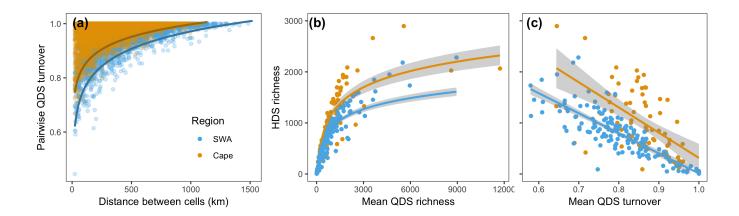

Figure 2: Regressions involving plant species richness and turnover. Species turnover (as Jaccards distance) between QDS-pairs increases as pairs are more geographically separated (a). Species turnover was calculated for all possible pairs of cells, but only the turnover values for a random 5000 pairs in each region have been plotted, for clarity. Fitted lines represent the 5%-quantile regressions of turnover as a function of log-distance for each region separately. Following a 5%-quantile regression of turnover as a function of log-distance with region as a categorical variable (Table 2), a significant interaction between distance and region was found (P < 0.001), such that the Cape positively effects the distance slope term. Scatter-plots of HDS-scale species richness against the average QDS-scale richness in a given HDS (b) and the average species turnover between QDS in a given HDS (c). Curves represent simples linear regressions of HDS richness against these two respective independent variables (note, mean QDS richness was $\log(x + 1)$ -transformed), separately for each region, for illustration of the two regions' differences, for interpretation alongside Table 3.
