9 Abstract

- 10 Aim: To quantify the explanatory power of heterogeneity in predicting plant species richness and turnover
- 11 here in the Greater Cape Floristic Region and in the Southwest Australia Floristic Region. We compare the
- 12 environmental heterogeneity in each region, how species richness and turnover interact in each region to
- 13 produce the observed patterns of richness, and what different forms of environmental heterogeneity better
- 14 predict richness in each region. We expect the Cape to be more heterogeneous in most environmental axes,
- 15 and at a finer grain, such that the consequent high levels of species turnover explain the Cape's greater
- 16 species richness per unit area. We also conjecture that edaphic heterogeneity will be an important factor in
- 17 predicting richness in SW Australia.
- 18 Location: The Greater Cape Floristic Region (GCFR) in southwest Africa, and the Southwest Australia
- 19 Floristic Region (SWAFR)
- 20 Taxon: Vascular plants
- Methods: Geospatial data, floral occurrence data \rightarrow regression analyses, non-parametric statistics
- 22 Results:
- 23 Main conclusions:
- 24 Keywords: biodiversity, environmental heterogeneity, fynbos, Greater Cape Floristic Region, kwongan,
- 25 macroecology, species richness, species turnover, vascular plants, Southwest Australia Floristic Region

30 1 Introduction

- 31 Biodiversity represents the variety of living things, and the variety of ecological and evolutionary processes
- 32 responsible for it (Bøhn & Amundsen, 2004). Studying the distribution of biodiversity in space is a major
- 33 avenue of biological research (???; Kreft & Jetz, 2007). Regional-scale geographic patterns in species richness

have long been studied, particularly in biodiversity hotspots (Cook et al., 2015). The spatial distribution of

35 species richness can be explained in terms of the physical environment. Properties of the environment have

- 36 been suggested to influence species richness in three ways: (i) productivity, water, and energy to enable
- 37 organismal growth, and resources (i.e. niche space) to support a wider range of species (Gaston, 2000; Kreft
- 38 & Jetz, 2007; Mouchet et al., 2015); (ii) stability, which enables species' persistence; and (iii) heterogeneity,
- 39 which enables ecological speciation and possible barriers to gene flow, and with a wider variety of
- 40 environments to facilitate species' co-existence (Thuiller et al., 2006; Mouchet et al., 2015; Cramer &
- 41 Verboom, 2016). The physical environment, then, can be used to explain species richness in a
- 42 local-deterministic sense, and in a historical context (Ricklefs, 1987).
- 43 The maintenance of species richness, particularly the coexistence of high numbers of species in biodiversity
- 44 hotspots, is often regarded as "paradoxical" (Hart et al., 2017), and is a central problem in ecology (Ricklefs,
- 45 1987; Kreft & Jetz, 2007; Hart et al., 2017). Species richness is constrained by the ability of habitats to
- 46 support a variety of species—its ecological carrying capacity (Mateo et al., 2017). This is exemplified in
- 47 approaches to modelling species richness as a function of environmental predictors in a correlative framework
- 48 ("macro-ecological models"; Mateo et al., 2017). Macro-ecological models of species richness implicitly
- 49 assume that communities are saturated, following species-area and species-energy relationships, and at
- 50 equilibrium with the environment (Mateo et al., 2017).
- A solution to the paradox of species coexistence is environmental heterogeneity (EH): a more heterogeneous
- 52 environment has a larger environmental space, and can thus facilitate co-existence between species at the
- 53 scale of that heterogeneity. EH can also stimulate ecological speciation, should the region be environmentally
- 54 stable over evolutionary time-scales. Heterogeneity in the physical environment is known to be positively
- associated with species richness (Rensburg et al., 2002; Hart et al., 2017), and has been demonstrated to do
- 56 so across many taxa—e.g. Canadian butterflies (???), European vertebrates (Mouchet et al., 2015), South
- 57 African birds (Rensburg et al., 2002), in communities along marine continental margins (Levin et al., 2010),
- 58 French scarab beetles (Lobo et al., 2004), and for global terrestrial plants (Kreft & Jetz, 2007). The spatial
- scale of heterogeneity, or "grain" of the environment, is important to consider (Hart et al., 2017), in the same
- 60 way that the spatial of absolute environmental conditions has also been considered (???; Baudena et al.,
- 61 2015; Mouchet et al., 2015). Species co-existence and biodiversity maintenance is indeed suggested to be
- 62 scale-dependent (Hart et al., 2017).
- 63 EH is often under-represented in macro-ecological models of species richness, and has recently been found to
- 64 explain up to ca. 95% of biome level species richness across South Africa (Cramer & Verboom, 2016).
- 65 Models that include EH yield better estimates of the richness of the Cape flora, as they account for the role
- 66 heterogeneous environments such as those in the Cape facilitate species coexistence (Thuiller et al., 2006;
- 67 Cramer & Verboom, 2016). Mediterranean-type terrestrial biodiversity hotspots, such as the Cape flora
- 68 included in the models by Cramer & Verboom (2016), present interesting study systems in which to
- 69 investigate the relationship between the environment and species richness. These systems exhibit far greater
- 70 species richness than predicted by their areas, productivities and latitudes (Cowling et al., 1996; Kreft &
- 71 Jetz, 2007). There are five Mediterranean biodiversity hotspots on Earth: the California Floristic Province,
- 72 the Mediterranean Basin, the Chilean Winter Rainfall-Valdivian Forests, the Greater Cape Floristic Region,
- and the Southwest Australia Floristic Region (Cowling et al., 1996; Hopper & Gioia, 2004; Cook et al., 2015).
- 74 These ecosystems have regular fire-cycles (Cowling et al., 1996), climatic buffering, and long term stability
- 75 (Kreft & Jetz, 2007), shrubby, sclerophyllous flora (Hopper & Gioia, 2004). Together, they account for ca.
- 76 20% of global vascular plant species, yet only ca. 5% of global land surface areas (Cowling et al., 1996).
- 77 Various hypotheses have been proposed to explain the high levels of plant species richness in these regions
- 77 Various hypotheses have been proposed to explain the high levels of plant species fitniness in these regions 78 (Cook et al., 2015). The species accumulation hypothesis states that the stability of these regions has allowed
- 79 many species to accrue. The species co-existence hypothesis states that these hotspots may facilitate greater
- 80 degrees of species co-existence in smaller spatial areas, due to fine-scale heterogeneity in their environments.
- degrees of species to existence in smaller species are some neutrogeners, in their environments
- 81 Indeed, EH has evolutionary implications too, stimulating ecological speciation across sharp environmental
- 82 gradients.
- 83 Both the Southwest Australia Floristic Region (SWAFR) and the Greater Cape Floristic Region (GCFR) are
- 84 Mediterranean-type biodiversity hotspots, particularly in terms of plant species. Where the GCFR (with an
- area of ca. $189,000 \text{ km}^2$) is known to contain about $11,400 \text{ plant species (about } 0.060 \text{ species per km}^2$), the

SWAFR (area of ca. 270,000 km²) has about 3,700 species (0.014 species per km²) (???). So, the GCFR has ca. 4.3 times as many species per km² as the SWAFR. The GCFR and SWAFR are appropriately often 87 compared, due to the similarities between their environments (e.g. oligotrophic soils, an oceanically buffered 88 moderate climate) and their plants' ecologies (Hopper & Gioia, 2004). These two regions present unique flora 89 90 out of the five Mediterranean systems, with high levels of endemism (Cowling et al., 1996), and many obligate fire-adapted species (Cowling et al., 1996). Similarities withstanding, the SWAFR is topographically 91 and edaphically distinct from the GCFR. The SWAFR former is topographically rather uniform 92 (i.e. flat)—uniquely so among the world's five Mediterranean-climate regions (Hopper & Gioia, 2004)). The 93 SWAFR possesses a mesoscale chronosequence dune system (Laliberte et al., 2014; Cook et al., 2015), while 94 95 the GCFR is mountainous, topographically heterogeneous, and therefore associated with a large degree of spatial climatic variability, with a fine-scale mosaic of geologies and soils (Cowling et al., 1996; Cramer et al., 96 2014; Verboom et al., 2017). Both regions have sources of edaphic heterogeneity, but at different scales. This 97 edaphic variability may aid in explaining the species richness in these regions (Beard et al., 2000; Verboom et 98 al., 2017). EH can stimulate ecological speciation, should the region be stable over evolutionary time-scales, 99 as is likely the case in both the GCFR and the SWAFR (Wardell-Johnson & Horwitz, 1996; Hopper & Gioia, 100 2004; Lambers et al., 2010; Cramer et al., 2014; Laliberte et al., 2014; Cook et al., 2015). For the GCFR, this 101 richness is largely known to result from long term climatic stability, and fine grain variation in geology and 102soils (Cramer et al., 2014). The question thus arises whether heterogeneity is a significant contributor to 103 SWAFR species richness as is likely the case in the GCFR. In the absence of topographic variability in the 104 105 SWAFR, it is proposed that the heterogeneity of that region is due to the juxtaposition of soil types (Laliberte et al., 2014; Cook et al., 2015), creating extreme edaphic variation. 106

107 1.1 Hypothesis-v1

- 108 Our main hypothesis is that the greater abiotic heterogeneity in the Cape, and the finer grain of that
- 109 heterogeneity, compared to that of the SWA, accounts for the Cape's greater species richness per unit area.
- 110 We expect the relationships between EH, species richness, and species turnover in these two regions to
- demonstrate this. As stated above, heterogeneous environments can (i) support diverse species assemblages,
- and (ii) stimulate ecological speciation. Thus, we expect species richness to covary with heterogeneity.
- 113 Additionally, as one moves across a heterogeneous landscape, we expect to find greater turnover in
- 114 community composition, as different environments support different species. Thus, areas of greater turnover
- should also be more rich, due to potential complementarity between neighbouring communities increasing
- total richness. Thus, we expect that EH positively influences species richness and species turnover, and that
- 117 species turnover itself positively influences species richness.

118 1.2 Hypothesis-v2

- 119 Aim: This study investigates the role EH plays in explaining vascular plant species richness in the Cape and
- 120 SWA. We compare the relative importance of heterogeneity between the two regions, as heterogeneity has the
- 121 evolutionary role of facilitating speciation, and the ecological role of supporting diverse species assemblages.
- 122 Spatial scale of that heterogeneity is also considered, as the heterogeneity-richness relationship can vary with
- 123 habitat grain-size.
- 124 Our hypotheses concern the Cape and SWA's environments and floras. Our main hypothesis is that the Cape
- 125 possesses greater abiotic heterogeneity, and at finer grain, compared to SWA, such as to explain the Cape's
- 126 greater species richness per unit area, and proposed greater levels of species turnover between areas. We also
- conjecture that the heterogeneity that predicts species richness in SWA will be more pronounced in terms of
- edaphic variables. Here we attempt to assess six key predictions of this hypothesis, additionally investigating
- 129 a seventh prediction to test the conjectured role of edaphic heterogeneity in SWA. Dealing with the two
- 130 regions' environments, we assess (i) whether the Cape environment is more heterogeneous than that of SWA
- 131 and (ii) whether the Cape environment has more pronounced heterogeneity at finer scales than that of SWA.
- Dealing with the distribution of species in the two regions, we assess (iii) whether the Cape exhibits greater
- 133 levels of species turnover between areas, such as to (iv) explain the greater species richness per unit area of

- the Cape compared to SWA. Relating each regions' environment and flora, we finally assess (v) whether 134
- species richness and species turnover are adequately predicted by EH in both regions and whether (vii) 135
- 136 Species richness and species turnover are better predicted by different forms of EH in either region (e.g. the
- importance of edaphic heterogeneity in SWA). 137
- 138
- We employ classical statistical methods to analyse publicly available geospatial and species occurrence 139
- 140 datasets.

2 Materials and methods 141

2.1Overview 142

- These analyses required definitions of the boundaries of the two regions, environmental data for each, and 143
- geospatially-explicit vascular plant occurrence records, all based on publicly available data. The 144
- environmental variables chosen (Table ??) for this study were intended to cover a reasonable spread of 145
- climatic, edaphic, and ecologically relevant environmental axes, and are not intended to be exhaustive. We 146
- selected variables describing topography (elevation), productivity (NDVI), soil status, and climate and 147
- climatic seasonality. 148
- We carried out this investigation using four principal spatial scales: 0.05° x 0.05° squares (the finest common 149
- resolution among the environmental data sources used), quarter degree squares (QDS) (Larsen et al., 2009),
- half degree squares (HDS) (Larsen et al., 2009) and three-quarter degree squares (3QDS). Note, at least for 151
- the Cape, most plant occurrence records are only accurate to QDS level. Thus, any analysis involving species 152
- data was necessary limited to scales above and including QDS. Analyses were performed in R v3.5.0 (R Core 153
- Team, 2018). Version-numbers of specific R packages used are presented in the bibliography, or in text where 154
- applicable. 155

177

2.2Environmental data sources 156

- Geospatially-explicit raster layers were acquired for a selection of environmental variables (Table ??), for the 157
- regions of interest. Here, the GCFR was treated as the areas occupied by the Succulent Karoo and Fynbos 158
- biomes in the current delineation of South Africa's biome boundaries (Mucina & Rutherford, 2006). The 159
- 160 SWAFR was treated as the areas occupied by the Southwest Australia savanna, Swan Coastal Plain Scrub
- and Woodlands, Jarrah-Karri forest and shrublands, Southwest Australia woodlands, Esperance mallee, and 161
- Coolgardie woodlands in the World Wildlife Fund Terrestrial Ecoregions dataset (Olson et al., 2001) in order 162
- 163 to closely match the currently delineated SWAFR (Gioia & Hopper, 2017, Hopper & Gioia (2004)). For the
- sake of readability, we shall refer to the GCFR and SWAFR simply as the Cape and SWA from hereon. 164
- 165 Raster data were re-projected to a common coordinate reference: WGS84 (NIMA, 2000), using the "rgdal"
- (???) package in R (R Core Team, 2018). All data were re-sampled to 0.05° resolution using the "resample" 166
- function in the R package "raster" (???), with the "bilinear" method. 167
- An emphasis was made on using satellite-derived environmental data in this work, in order to minimise 168
- differences in data quality and methodologies between the Cape and SWA. Additionally, satellite-derived 169
- 170 data have been shown to benefit regional-scale species distribution models (Deblauwe et al., 2016), thus
- motivating their use in this regional-scale study. The environmental data used in this study were derived 171
- from NASA's SRTM digital elevation model (Farr et al., 2007), NASA's MODIS/Terra spectroradiometric 172
- data for land surface temperature and NDVI, the Climate Hazards Group's CHIRPS rainfall dataset (Funk 173
- et al., 2015), and the International Soil Reference and Information Centre's SoilGrids250m edaphic dataset 174 (Hengl et al., 2017) (Table ??). SRTM and MODIS are entirely derived from satellite measurements, whereas
- 175
- 176 CHIRPS is interpolated from weather station data with satellite-derived radiometric measurements. SoilGrids250m is a machine-learning derived product, based on soil measurements as a function of many

- 178 covariates, including MODIS and STRM sources (see Hengl et al., 2017), using random-forests and other
- classification-tree-based methods, including gradient-boosting. For the soil data considered here (Table 1),
- 180 we used depth-interval weighted average values as the value for a particular soil variable in a given place.
- 181 Climatic and spectral data arise from satellites monitoring properties of the Earth's surface through time.
- We therefore use the mean annual values for rainfall, surface temperature, and NDVI across space in our
- analyses. Pronounced seasonality of rainfall is a known feature of Mediterranean systems (???). known
- to to timing, namely precipitation in the driest quarter (PDQ) and temperature in the ... describe!->

2.3 Plant occurrence data

185

- 186 Geospatially-explicit records of vascular plant occurrences were downloaded from the Global Biodiversity
- 187 Information Facility (GBIF, Table ??). Queries were made for tracheophyte records from within the borders
- of the Cape and SWA as treated here (GBIF, 24 July 2017, GBIF (24 July 2017)). Only records with defined
- 189 species and intra-specific ranks were kept. Intra-specific occurrences were treated as simply being
- 190 representative of their species. This resulted in 1 unique species names in the Cape, and 1 in SWA.
- 191 We cleaned these data using the R package "taxise" (???, (???)) to check that these species names had
- 192 accepted-status among taxonomic databases. I queried two major taxonomic databases: the Global Name
- 193 Resolver (GNR), and the Taxonomic Name Resolution Service (TNRS). Should one of either service return
- at least one match for a given name, then that name was deemed accepted. Those names for which no full
- 195 binomial matches were found in either database were excluded from the final list of species. The number of
- 196 species names excluded totalled at 1 and 1 for the Cape and SWA respectively. Especially for SWA, these
- 197 numbers may be deemed appreciably high. But, the occurrence records that would be dropped, as a
- 198 consequence of these names' removals, seemed to be distributed randomly in geographic space in both
- 199 regions. As such, any effect of the loss of these records in this analysis is uniform within the two regions.
- 200 After the unaccepted names were removed, it was important to ensure that a species was not listed under
- 201 multiple synonyms. Such cases would skew the species richness data used in this study. In light of this, the
- 202 remaining names were queried in the Tropicos and Integrated Taxonomic Information System (ITIS)
- 203 databases for their known synonyms, using "taxize". These were collated to produce a nomenclatural
- 204 "thesaurus" for the Cape and SWA species. This consisted of a list of the accepted species names in a region,
- each associated with a list of known synonyms. I amended species' names in the GBIF occurrence data, in
- 206 order ensure species were listed under only one of these synonyms, as follows: For each entry in the
- 207 thesaurus, for each synonym of that entry, if that synonym appeared in the GBIF species list, I replaced all
- 208 appearances of that synonym in the species list with the original name from the thesaurus-entry that that
- 209 synonym came from.
- 210 Lastly, I removed any species from both regions that are invasive aliens or non-indigenous. Alien species lists
- 211 for plants in South Africa and Australia were acquired from the IUCN's Global Invasive Species Database
- 212 (http://www.iucngisd.org/gisd/).
- 213 The final total plant species richness in each region was 12991 and 8074 for the Cape and SWA respectively.
- These final collections of species occurrence records were converted to raster-layers, wherein pixel-values
- 215 represented the species, genus and family richness of vascular plants within that pixel. These rasters were
- 216 produced at QDS, HDS, and 3QDS resolutions.

217 **2.4** Analyses

218 2.4.1 Quantifying environmental heterogeneity

- 219 First, in order to assess predictions (i) and (ii), we needed to describe the EH in both regions. Using the R
- 220 package "raster" (???), we used a modified version of the "roughness" index in the "terrain" function: for a
- 221 three by three neighbourhood of cells, our index of roughness is the average square-root of the squared
- difference between each of the n neighbour cells' values x_i and the central focal cell's value x_{focal} :

$$Roughness = \frac{1}{n} \sqrt{\sum_{i=1}^{n} (x_{focal} - x_i)^2}$$
 (1)

Note, in order to use as much data from within regions' borders as possible, roughnes swas computed if a 223 focal cell had at least one neighbour cell—that is, roughness is defined where $n_{x_{focal}} \geq 1$. Using this index of 224 heterogeneity, we produced raster layers of each of our nine environmental variable's heterogeneity. We 225 226 compared the distributions of roughness values in each variable in each region with non-parametric Mann-Whitney U-tests, as almost all variables could not be normalised by log-transformations. We also 227 compare the effect size of the Cape vs SWA using the "common language effect size" (CLES), using the R 228 package "canprot". The CLES is the proportion of all pairwise comparisons between two sample groups 229 observations where one group's value is greater than the other. In our case, of all pairwise comparisons of a 230 variable's roughness values between the Cape and SWA, we calculated the CLES as the proportion of pairs 231 where Cape roughness values were greater than that of SWA. This allowed us to assess prediction (i). To 232 compare the spatial scales of heterogeneity (prediction [(ii)] [Hypothesis-v2) between each region, we repeated 233 this analysis at all four spatial scales. Once again, this entailed recalculating the roughness layer for each 234 variable after the original layer (0.05 degrees resolution) had been rescaled to each of the coarser resolutions. 235

2.4.2 Relating species richness and species turnover

236

Regarding predictions (iii) and (iv), we wished to compare the relative importance of species turnover in each region as a predictor of species richness.

First, for (iii), we compared the degree of species turnover in general in each region by computing all pairwise Jaccard distances (???) between QDS' communities. We then regressed these turnover values for each pair of cells against the physical distance between the centres of those cells. The range of turnover values was found to be highest at small distances (Figure 1A), and indeed complete species turnover between cell pairs was observed at all distances. Thus we used quantile regressions of the 5% quantile of species turnover as a function of geographic distances (using "quantreg" (???) in R). This allowed us to compare the lower bounds of species turnover between the Cape and SWA.

Regarding prediction (iv), to test how turnover between sites predicts richness across rites, we regressed the 246 species richness in coarse scale cells against the average richness of and average turnover between the 247 constituent fine scale cells within a the coarse scale cell. Moreover, average turnover between fine scale cells 248 excluded turnover values between a cell j and itself (necessarily 0), and only included turnover values 249 between between cell j and k and not between k and j (as these are necessarily the same). We focussed on 250 this relationship with HDS as the coarse scale and QDS as the fine scale—as there are four QDS within each 251 HDS, and QDS was the highest precision to which our species data were recorded. Average QDS richness for 252 a given HDS-cell $(\overline{S_{QDS}}_i)$, then, is based on j=4 QDS-cells, and is treated here as 253

$$\overline{S_{QDS}}_i = \frac{1}{j} \sum_{i=1}^4 S_{QDS_j}.$$
 (2)

Average QDS turnover for a given HDS $(\overline{T_{QDS}}_i)$, based on $n = \binom{j=4}{2} = 6$ QDS pairs (namely pairs $QDS_{1,2}$, $QDS_{1,3}$, $QDS_{1,4}$, $QDS_{2,3}$, $QDS_{2,4}$ and $QDS_{3,4}$) is treated here as

$$\overline{T_{QDS}}_i = \frac{1}{n} \sum_{n=1}^{6} T_{QDS_n}.$$
 (3)

256 Thus, we regress coarse scale richness as follows:

$$\widehat{S_{HDS_i}} = \beta_0 + \beta_1 \overline{S_{QDS_i}} + \beta_2 \overline{T_{QDS_i}} + \beta_3 SW A_i + \beta_4 \overline{S_{QDS_i}} SW A_i + \beta_5 \overline{T_{QDS_i}} SW A_i + \epsilon_i$$

$$(4)$$

where $\epsilon \sim N(\bar{x}, \sigma^2)$, and $\overline{S_{QDS}}$ is log(x+1)-transformed. This model allows us to compare the

- 258 spatial-scaling drivers of species richness in either region: whether coarse scale increases in species richness
- 259 are determined more by (a) being composed of richer—but more similar—communities or by (b) being
- 260 composed of many different communities. These represent the two logical extremes.

261 2.4.3 Predicting species richness and turnover with environmental heterogeneity

262 3 Results

263 3.1 Describing environmental heterogeneity numerically across scales

- 264 Across all variables considered, the Cape is more environmentally heterogeneous in the majority of pairwise
- comparisons of grid-cells (CLES > 0.50, Mann-Whitney U-test: P < 0.05, Figure 1). The Cape is thus more
- environmentally heterogeneous than SWA overall, but the degree to which it is more heterogeneous varies
- 267 between environmental variables. These effects vary somewhat with the spatial scale concerned. In some
- variables, the differentiation between Cape and SWA heterogeneity lessens at coarser scales (Figure 1).
- 269 Indeed, when comparing the overall ranking and medians of Cape vs SWA roughness values for each variable,
- 270 we only find non-significant differences at the coarser 3QDS scale (Mann-Whitney U tests, P > 0.05, Figure
- 271 1).
- 272 Most obviously, and as expected, topographic heterogeneity is greatest in the Cape (Figure 1a). Though
- 273 SWA has a slightly wider distribution of elevational roughness values at coarse scales (e.g. 3QDS, Figure 1a)
- 274 compared to fine scales (0.05°) , so does the Cape. As such, the relative difference between the two regions
- seems invariant with spatial scale ($CLES \approx 0.95$, Figure 1).
- 276 This concurs with our expectations, as the Cape is mountainous and known to have steep elevational
- 277 gradients (???), while SWA is much more topographically uniform.
- 278 Intuitively, then, elevation serves as a "benchmark test" for our comparisons of EH here, as it is well known
- and expected that the Cape should be more elevationally heterogeneous than SWA. Additionally, we can
- conclude that although there are greater extreme values of Cape elevational roughness at 0.05° x 0.05° scales,
- larger sections of land (i.e. 3QDS-cells) are are more different from each other in the Cape than the same
- 282 sized sections are different from each other in SWA.
- 283 Climatic heterogeneity presents less differentation between the Cape and SWA than elevational roughness,
- though still the Cape predominates (Figure ??b). Notably, the difference between Cape and SWA mean
- annual rainfall and land surface temperature heterogeneity lessens when considered at coarse spatial scales
- 286 (3QDS scale, Figure ??b). Rainfall seasonality (PDQ), however, is similarly more heterogeneous in the Cape
- 287 across all spatial scales considered.
- 288 Biological productivity, as measured by NDVI, varies spatially to a similar extent in the Cape and SWA
- 289 (i.e. is more similarly heterogeneous, CLES < 0.60, Figure 1c).
- 290 Concerning edaphic variables (Figure 1d), the Cape and SWA are similarly heterogeneous at coarser scales,
- 291 particularly in terms of CEC and Soil C.
- 292 We can differentiate the Cape and SWA environments based on which environmental axes are more
- 293 heterogeneous in either region, as they differ somewhat in this regard.

3.2 Species richness as determined by species turnover

295 3.2.1 Quantifying the "general" degree of species turnover in each region

- 296 Following quantile regressions of the 5%-quantile of pairwise species turnover against the distance between
- 297 pairs' sites (Figure 2a), there is evidence that SWA exhibits a lower lowermost-bound of observed species
- 298 turnover. This is because of the relative positive influence of a site's being "from the Cape", as opposed to
- SWA, on the 5%-quantile of species turnover ("Cape"-term, P < 0.001, Table 2). As expected, species
- 300 turnover was greatest between distant pairs of QDS (P < 0.001, Table 2, Figure 2a).

301 3.2.2 How species richness is determined by species turnover

302 Logic: Richness @ coarse scale ~ \sum Richness @ finer scale + \sum Turnover @ finer scale

4 Discussion

294

303

- 304 Conclusion: The Cape is more generally environmentally heterogeneous than the SWA, as expected (see
- 305 prediction (i)). Though, there are cases where the SWA is arguably at-least-as-heterogeneous as the Cape,
- and we can observe here extreme regions of high edaphic heterogeneity, at fine scales, in SWA. These surpass
- 307 the edaphic heterogeneity of the Cape, supporting our seventh prediction/conjecture.
- 308 We also have support for prediction (ii), as seen in Fig. ??.
- 309 I have provided support for the hypothesis that the difference in plant species richness between the GCFR
- and SWAFR is accounted for by the fact that the GCFR is more abiotically heterogeneous than the SWAFR.
- 311 As expected, the GCFR is shown to possess (i) a quantifiably more heterogeneous environment, and (ii) is
- 312 heterogeneous at a finer spatial scale than the SWAFR. I have shown that vascular plant species richness (iii)
- 313 can be explained in terms of environmental conditions, including environmental heterogeneity, in both the
- 314 GCFR and SWAFR. Also, I have shown that (iv) the set of environmental axes that explain plant species
- 315 richness, both absolute and as heterogeneity, differs between the GCFR and SWAFR. These findings
- 316 contribute towards an understanding of the ecological conditions that facilitate species coexistence (and likely
- 317 stimulate ecological speciation) in these two regions.
- 318 These two regions present differentiable environmental spaces, each with heterogeneity varying across spatial
- scales. The clear separation of the regions' topographic features is as expected (Figures ??A, ??). Indeed,
- 320 topography seems to be the most striking distinction between the regions. The Cape region has been found
- 321 previously to have the second highest median topographic heterogeneity of the five Mediterranean-climate
- 322 regions (Bradshaw & Cowling, 2014). The GCFR has a much wider range of scales exhibited in the
- 323 heterogeneity across its environmental axes. Notably, each region has finer scale heterogeneity in some
- 324 variables, and coarser scale in others—neither region is necessarily more fine or coarse than the other, as it
- 325 depends on the variable concerned. BRT-models of species richness in both regions reveal species richness to
- depend on those environmental axes that differentiate the two regions (Figures ??), ??). The importance of
- variables is also shown to vary with spatial scale (Figure ??), as previously suggested may be the case when
- modelling geographic patterns of biodiversity (Baudena et al., 2015). Indeed, as Cowling et al. (1996)
- 329 describes differing patterns of species richness across spatial scales, so do the predictors of those patterns
- 330 vary with scale (Hart et al., 2017).
- 331 The fact that a combination of absolute and roughness variables is also as predicted by the hypothesis in this
- 332 study. In the models developed by Cramer & Verboom (2016) for South Africa, roughness in topography was
- 333 largely superseded as an important predictor of species richness by other roughness variables. My models,
- however, did not show this. Similar to the study by Rensburg et al. (2002), my models revealed roughness in
- 335 topography and other variables to be important. Although, Rensburg et al. (2002) considered differences
- 336 within pixels, as opposed to this study, which considered differences between pixels. My models, those of
- 337 Cramer & Verboom (2016), and those of Rensburg et al. (2002), do not all concur as to the role of roughness

in elevation vs. more biologically meaningful variables in explaining species richness. The source of these discrepancies is unclear, though no doubt complex. The complements of environmental variables and methodologies used in these studies do differ, limiting extensive comparison between these analyses.

340 methodologies used in these studies do differ, limiting extensive comparison between these analyses. The determinants of vascular plant species are shown to be region specific (Figures ??, ??, ??). The 341 importance of MAP and roughness in rainfall seasonality (PCV) in predicting richness in the SWAFR 342 343 (Figure ??I, ??J), aligns with the steep climatic gradients observed there (Cook et al., 2015). The soil variables that determine plant species richness in the model for the SWAFR (Figures ??K, ??L) differ to 344 those that determine richness in the GCFR (Figures ??G, ??H), further highlighting the edaphic differences 345 between these two regions. Although both are nutrient leached systems, the SWAFR is flat, with 346 soil-chronosequences (Laliberte et al., 2014; Cook et al., 2015), while the GCFR is mountainous (Cowling et 347 al., 1996; Cramer et al., 2014; Verboom et al., 2017). The importance of roughness in soil density, and 348 absolute texture, in the SWAFR (Figures ??K, ??L) highlights the changes in soil that are associable with 349 age of the substrate (e.g. particle size) as being biologically relevant to species richness. The positive effect 350 351 of soil clay content on species richness in the SWAFR aligns with the findings of Laliberte et al. (2014) that richness in the SWAFR increases with soil age. 352

NDVI is more heterogeneous across the GCFR than the SWAFR (Figures ??A). The fact that thermal 353 variables tend to be more rough in the GCFR (Figure ??A) is likely due to possible covariance of the 354 MODIS/Terra products with topography, as MODIS data used here describes land surface temperature. As 355 356 the GCFR is topographically rugged, the roughness of NDVI may arise from this. Despite this, NDVI is an integrating variable, which captures information about productivity, light availability, and soil nutrients 357 (Power et al., 2017). The fact that absolute NDVI contributes to predicting species richness in the GCFR, 358 especially at finer spatial scales (Figure ??E) demonstrates the role of ecological productivity in facilitating 359 the coexistence diverse species assemblages. Environmental heterogeneity, then, is integral to explaining 360 patterns of species richness, but must be considered along with resource- and energy-availability axes. In so 361 362 much as a diverse environmental space supports more species, the materials and productivity required for biota to thrive are also needed to support species (????; Gaston, 2000; Bøhn & Amundsen, 2004; Kreft & 363 Jetz, 2007). As such, my findings, along with those of previous studies (Rensburg et al., 2002; Thuiller et al., 364 2006; Kreft & Jetz, 2007; Cramer & Verboom, 2016), suggest that there is ecological and evolutionary 365 consequence to resource availability and environmental heterogeneity, in that they tend to be positively 366 367 associated with species richness.

The combined BRT-model of species richness for both regions reveals soil clay content as an important predictor, at coarse spatial scales, despite this variable not being particularly important within each region separately (Figure ??). Though this model does not strictly consider the regions as separate, this finding may indicate that the relationship between clay content and species richness differs between the regions. So far as clay content can be used to predict species richness, it matters more to those predictions when applied to large sections (i.e. coarse scales) of each regions.

Kreft & Jetz (2007) modelled global terrestrial vascular plant species richness, which focussed on primarily 374 absolute environmental values, underestimated the richness of the Cape flora. Though Kreft & Jetz (2007) 375 did include topographic heterogeneity in their predictor set, topography is often a proxy for more biologically 376 meaningful variables (Cramer & Verboom, 2016). This explains why the inclusion of these variables (377 e.g. roughness in mean annual precipitation) yields more accurate predictions of species richness. Indeed, 378 Thuiller et al. (2006) also included topographic heterogeneity. Cramer & Verboom (2016) described 68% of 379 species richness at the QDS scale across South Africa. Regarding the GCFR, depending on whether one 380 consults pseudo- R^2 (Table 3), the ratio of mean predicted to observed richness per grid-cell (Table 5), or the 381 distributions of predicted vs. observed richness values per grid-cell (Figure ??), I have achieved a similarly 382 suitable level of predictive accuracy. There is, though, still unexplained species richness in light of my models. 383 384 As Cramer & Verboom (2016), Rensburg et al. (2002), Thuiller et al. (2006), and Mouchet et al. (2015) have done, these macro-ecological models are a-historical. Evolutionary considerations of species richness in 385 geographic space are worthwhile, especially in regions with environments stable over evolutionary time. 386

The findings here are correlative. There are, however, many proposed mechanisms to explain the correlative signals demonstrated here. My findings support the hypothesis that Mediterranean systems' plant species

richness is a function of spatial variability in environmental conditions. This can stimulate diversification, and maintain that diversity by providing a range of habitats for species co-existence. Oligtrophic soils can stimulate an increase in functional diversity, through the evolution of diverse nutrient acquisition strategies (Lambers et al., 2010; Verboom et al., 2017) (e.g. sclerophylly (Cramer et al., 2014; Cook et al., 2015)). An aspect of the environment I have neglected to consider is fire, shown to also contribute to predictions here in the GCFR (Cramer & Verboom, 2016). Cardillo (2012) have shown the structuring forces behind species co-occurrence patterns, and thus likely species richness, differ between species-pairs with different post-fire responses and those with similar post-fire responses.

Though the GCFR was correctly predicted to have, on average, more species per grid-cell at HDS and 3QDS 397 scales than the SWAFR, this was not the case for QDS grid-cells (Table 5). This demonstrates that the 398 GCFR is indeed overall more rich in plant species than the SWAFR, but a given HDS in the SWAFR 399 contains fewer species than a given GCFR HDS. Thus, the greater richness in the GCFR is a product of 400 greater turnover in species at spatial scales no more coarse than the HDS. Species turnover is an interesting 401 402 aspect to species richness studies, as it species turnover is implicit to species-area and co-existence-area relationships (Hart et al., 2017). One could expect patterns of endemism and species turnover to concur with 403 patterns in environmental heterogeneity to some degree. 404

Following from the understanding that functionally diverse assemblages, which are more likely to be more 405 species rich, are likely to arise and/or occur in areas with diverse ecological pressures (Molina-Venegas et al., 406 407 2015), one would expect, then, heterogeneous habitats such as those in Mediterranean-type biodiversity 408 hotspots to exhibit high levels functional beta diversity along steep environmental gradients (Molina-Venegas et al., 2015). If the niches concerning these functions are phylogenetically conserved among those biota, then 409 one would also expect high levels of species and phylogenetic beta diversity along these gradients 410 (Molina-Venegas et al., 2015). This concurs with the notion put forward by Power et al. (2017), wherein 411 megadiverse systems such as these represent the results of "phylogenetic niche conservatism on a 412 413 heterogeneous landscape". Thus, species and phylogenetic turnover should covary with environmental heterogeneity in some way. Indeed, endemism, at certain scales, could also follow this pattern. Thuiller et al. 414 (2006) demonstrated that there is phylogenetic and biome related determinants of species richness. This 415 makes sense, in light of the difficulty of crossing biome boundaries in Mediterranean systems (Power et al., 4162017). NDVI and light availability, and the heterogeneity therein, are associated with high levels of floristic 417 418 turnover (Power et al., 2017). This may be indicative of ecological specialisation precluding species from crossing these boundaries, thus increasing the level of endemism within a region, while also increasing the 419 level of turnover, and thus likely species richness, along environmental gradients. Although, this may be 420 debated. Beard et al. (2000) state that the high levels of endemism in SWAFR are function of habitat 421 specialisation to soil mosaics. Cf. Laliberte et al. (2014), who say that this endemism is likely due to environmental filtering along these soil turnover sequences, as opposed to the juxtaposition of specialised 423 424 species along soil gradients.

I have demonstrated support for the idea that environmental heterogeneity is positively associated with species richness, particularly Mediterranean systems. In the SWAFR and the GCFR, high levels of endemism and biodiversity are also likely the results of long-term landscape and climatic stability (Hopper, 1979). Thus, the roles of environmental variability through space, and stability through time, are the two main ways in which the environment relates to biodiversity in these regions.

Table captions

431 **Table 1**

432 Data sources used in this study. Abbreviations are as follows:.

433 Table 2

- Estimated coefficients and significances (P-value) following quantile regression of the 5%-quantile ($\tau = 0.05$)
- 435 of pairwise species turnover (as Jaccards distance) as a function of the geographic distance (km,
- 436 log-transformed) between QDS cells. The Cape term represents the difference between Cape and SWA
- 437 species turnover, for a given geographic distance.

438 **Table 3**

- 439 Estimated coefficients and significances (P-value) following multiple linear regression of HDS species richness
- 440 (S_{HDS}) against the mean QDS species richness $(\overline{S_{QDS}}, \text{ Equation (2)})$ and turnover (Jaccards distance, $\overline{J_{QDS}}$,
- 441 Equation (3)) within a given HDS, of the form in Equation (4). The Cape was fit as the baseline, hence SWA
- 442 represents the categorical term here. This was model was better fitting than a similar model without a region
- category ($\Delta AIC = 90.56$). Note, this model does not represent those curves plot in Figures 2 and ?? (there,
- 444 the curves are from simple linear regressions of the variables in each panel, separated by region).

445 **Table 4**

- 446 Comparisons of Akaike information criterion values (small sample-size-corrected, AICc) of various
- 447 geographically weighted regressions (GWR) of log-transformed species richness as a function of various sets
- 448 of environmental variables. Models were fit for the Cape and SWA richness and environmental data both
- 449 separately and together. GWR methods preclude the need for a categorical predictor for the Cape vs SWA,
- 450 as the longitudinal (and to a lesser extent latitudinal) differences between the regions allows local regression
- 451 coefficients in each region to differ.

452 Figure captions

453 Captions are also repeated alongside their respective figures for readability.

454 Figure 1

- 455 Comparisons of different types of environmental heterogeneity in the Cape and SWA—namely for (a)
- 456 elevation, (b) climatic variables, (c) NDVI and (d) soil variables—in each panel consisting of three sub-panels
- 457 per variable type. The upper row of panels shows example distributions of roughness values (Equation (1)),
- 458 showing the different extremes in environmental heterogeneity observed in each region when compared at fine
- 459 (0.05°) and coarse (3QDS) scales. Each distribution has under it area 1. Distributions were constructed with
- 460 Gaussian kernels, with bandwidth following Silverman's "rule of thumb" (???). In the lower row of panels,
- 461 these distributions of roughness values were compared between the Cape and SWA at each of the four spatial
- 462 scales, not just 0.05° and 3QDS, using non-parametric Mann-Whitney U-tests to test for differences. The
- 463 "common language effect size" (CLES, see text) describes these differences (b). U-tests for almost all
- 464 environmental variables yielded significant differences (P < 0.05) between Cape and SWA values (NS,
- 465 non-significant differences).

466 Figure 2

- 467 Regressions involving plant species richness and turnover. Species turnover (as Jaccards distance) between
- 468 QDS-pairs increases as pairs are more geographically separated (a). Species turnover was calculated for all
- possible pairs of cells, but only the turnover values for a random 5000 pairs in each region have been plotted,
- 470 for clarity. Fitted lines represent the 5%-quantile regressions of turnover as a function of log-distance for each

- 471 region separately. Following a 5%-quantile regression of turnover as a function of log-distance with region as
- 472 a categorical variable (Table 2), a significant interaction between distance and region was found (P < 0.001),
- 473 such that the Cape positively effects the distance slope term. Scatter-plots of HDS-scale species richness
- 474 against the average QDS-scale richness in a given HDS (b) and the average species turnover between QDS in
- 475 a given HDS (c). Curves represent simples linear regressions of HDS richness against these two respective
- 476 independent variables (note, mean QDS richness was log(x + 1)-transformed), separately for each region, for
- 477 illustration of the two regions' differences, for interpretation alongside Table 3.

Plant species occurrence	GBIF	@GBIFCape, @GBIFSWA

Table 2: Estimated coefficients and significances (P-value) following quantile regression of the 5%-quantile ($\tau=0.05$) of pairwise species turnover (as Jaccards distance) as a function of the geographic distance (km, log-transformed) between QDS cells. The Cape term represents the difference between Cape and SWA species turnover, for a given geographic distance.

Term	Estimate	P-value
Intercept	-0.311	< 0.001
log(Distance between cells)	0.093	< 0.001
Cape	0.388	< 0.001
$log(Distance between cells) \times Cape$	-0.026	< 0.001

Table 3: Estimated coefficients and significances (P-value) following multiple linear regression of HDS species richness (S_{HDS}) against the mean QDS species richness (\overline{S}_{QDS} , Equation (2)) and turnover (Jaccards distance, \overline{J}_{QDS} , Equation (3)) within a given HDS, of the form in Equation (4). The Cape was fit as the baseline, hence SWA represents the categorical term here. This was model was better fitting than a similar model without a region category ($\Delta AIC = 90.56$). Note, this model does not represent those curves plot in Figures 2 and ?? (there, the curves are from simple linear regressions of the variables in each panel, separated by region).

Term	Estimate	P-value
Intercept	-3062.297	0.000
$log(\overline{S_{QDS}} + 1)$	595.574	0.000
$\overline{J_{QDS}}$	338.589	0.534
SWA	2905.604	0.001
$log(\overline{S_{QDS}} + 1) \times SWA$	-333.908	0.000
$\overline{J_{QDS}} \times \text{SWA}$	-1246.109	0.073

Table 4: Comparisons of Akaike information criterion values (small sample-size-corrected, AICc) of various geographically weighted regressions (GWR) of log-transformed species richness as a function of various sets of environmental variables. Models were fit for the Cape and SWA richness and environmental data both separately and together. GWR methods preclude the need for a categorical predictor for the Cape vs SWA, as the longitudinal (and to a lesser extent latitudinal) differences between the regions allows local regression coefficients in each region to differ.

Model predictors	AICc	$\Delta AICc$	w_{AICc}
Cape:			
Absolute variables	2112.49	0.00	1.00
Non-elevation variables	2179.35	66.86	0.00
All	2192.59	80.10	0.00
Soil variables	2197.76	85.28	0.00
Roughness variables	2208.43	95.94	0.00
Non-soil variables	2218.08	105.59	0.00
Elevation	2267.30	154.81	0.00
Null	3099.37	986.89	0.00
SWA:			
Absolute variables	826.47	0.00	0.69
Non-elevation variables	828.29	1.82	0.28
All	833.44	6.97	0.02
Soil variables	835.92	9.45	0.01
Non-soil variables	848.57	22.11	0.00

Null	27172.21	26345.74	0.00
Both:			
Absolute variables	1286.27	0.00	1.00
Roughness variables	1338.16	51.89	0.00
Non-elevation variables	1364.26	77.98	0.00
Elevation	1371.30	85.02	0.00
Soil variables	1371.47	85.19	0.00
Non-soil variables	1380.38	94.11	0.00
All	1390.78	104.50	0.00
Null	1404.05	117.78	0.00

579 Figures

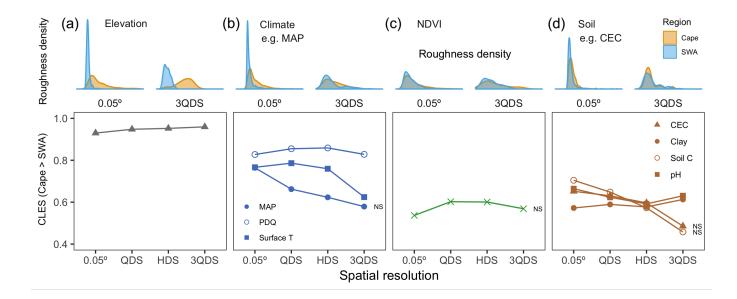

Figure 1: Comparisons of different types of environmental heterogeneity in the Cape and SWA—namely for (a) elevation, (b) climatic variables, (c) NDVI and (d) soil variables—in each panel consisting of three sub-panels per variable type. The upper row of panels shows example distributions of roughness values (Equation (1)), showing the different extremes in environmental heterogeneity observed in each region when compared at fine (0.05°) and coarse (3QDS) scales. Each distribution has under it area 1. Distributions were constructed with Gaussian kernels, with bandwidth following Silverman's "rule of thumb" (???). In the lower row of panels, these distributions of roughness values were compared between the Cape and SWA at each of the four spatial scales, not just 0.05° and 3QDS, using non-parametric Mann-Whitney U-tests to test for differences. The "common language effect size" (CLES, see text) describes these differences (b). U-tests for almost all environmental variables yielded significant differences (P < 0.05) between Cape and SWA values (NS, non-significant differences).

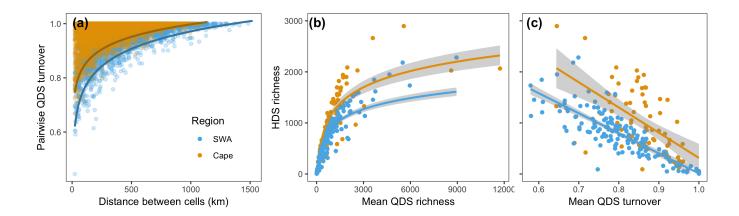

Figure 2: Regressions involving plant species richness and turnover. Species turnover (as Jaccards distance) between QDS-pairs increases as pairs are more geographically separated (a). Species turnover was calculated for all possible pairs of cells, but only the turnover values for a random 5000 pairs in each region have been plotted, for clarity. Fitted lines represent the 5%-quantile regressions of turnover as a function of log-distance for each region separately. Following a 5%-quantile regression of turnover as a function of log-distance with region as a categorical variable (Table 2), a significant interaction between distance and region was found (P < 0.001), such that the Cape positively effects the distance slope term. Scatter-plots of HDS-scale species richness against the average QDS-scale richness in a given HDS (b) and the average species turnover between QDS in a given HDS (c). Curves represent simples linear regressions of HDS richness against these two respective independent variables (note, mean QDS richness was $\log(x + 1)$ -transformed), separately for each region, for illustration of the two regions' differences, for interpretation alongside Table 3.
